FOR IMMEDIATE RELEASE

Opening the immune system’s “black box”
LJI researchers first to directly track how the latest HIV vaccine candidate elicits a successful antibody response, revealing crucial immunological features and barriers

November 28, 2016

LA JOLLA, CA— In the global quest to get the ongoing AIDS epidemic under control, dozens of HIV vaccine candidates have been tested in clinical trials but a safe and effective HIV vaccine has yet to emerge. Until now, researchers trying to understand why so many attempts have failed, had been limited to measuring antibody titers in peripheral blood weeks or months after immunization with a vaccine candidate, while germinal centers, the central hub for the generation and fine-tuning of high-affinity antibodies, had remained something of a “black box.”

Now, for the very first time, researchers at La Jolla Institute for Allergy and Immunology were able to directly probe germinal centers and shed light on the immunological processes by which a vaccine elicits a protective immune response. Their findings, published in the current issue of Cell Reports, revealed important immunological features and bottlenecks that determine whether immunization is successful and provide a valuable tool to track the potential of novel HIV vaccine candidates in upcoming human phase I clinical trials.

“When you can’t measure what’s going on in germinal centers to find out what went wrong, you don’t know how to best move forward,” says the study’s lead author Shane Crotty, Ph.D., a professor in the Institute’s Division of Vaccine Discovery. “This has been a long standing problem in immunology and the failure to develop a HIV vaccine has highlighted the problem because it has proven particularly difficult to generate protective immunity against the virus.”

More than two million people are infected with HIV every year. Although available treatment options can effectively stall the virus, only roughly half of HIV-infected individuals have access to antiviral drugs. Vaccines are the most effective means to prevent HIV infections and a preventive HIV vaccine would have a tremendous impact on global health. For any vaccine to be successful, it has to induce broadly “neutralizing” antibodies (nAbs), which render an invading pathogen harmless before it gets a chance to infect its host.

Before B cells can start producing nAbs they have to team up with so-called follicular helper T cells (T<sub>FH</sub> cells) in germinal centers, which are located in peripheral lymph nodes. There B cells undergo a tightly orchestrated, multi-step education and maturation process, which selectively
promotes the proliferation of B cells that produce high-affinity antibodies and weeds out those that produce less potent ones. It has been speculated that germinal centers are very important for HIV neutralizing antibody responses.

Trying to find a way to directly track the characteristics of a successful nAb response within germinal centers, Colin Havenar-Daughton, Ph.D., the study’s first author, wondered whether lymph node fine needle aspirates (LN FNAs), which have long been used by oncologists to detect the presence of metastases, could provide critical information.

He teamed up with experts at the Yerkes National Primate Research Center to follow a cohort of 12 rhesus monkeys that had been immunized with a novel HIV envelope protein trimer known as SOSIP.v5.2, which closely mimics the virus’ surface. That protein was developed by collaborators at Cornell and the University of Amsterdam. “These envelope proteins have just recently become available for immunizations and most likely will go into phase I human trials soon,” explain Havenar-Daughton.

In the current study the SOSIP protein elicited neutralizing antibodies in 9 out of 12 subjects, which is the best HIV neutralizing antibody response reported to date for a candidate HIV vaccine protein. “It was a very good response but if you go into humans you want everybody making neutralizing antibodies and not just some people,” he says. “We need to solve this problem.”

Havenar-Daughton thinks he may have found a way. “We could confirm that LN FNAs provide a valuable and informative window into germinal centers to explore the difference between immune responses that result in HIV neutralizing antibodies and those that didn’t,” he says. Adds Guido Silvestri, M.D., Chief of the Division of Microbiology & Immunology at the Yerkes National Primate Research Center, whose team performed the LN FNAs: "We are very excited about the validation of a very informative yet non-invasive sampling technology such as the fine needle aspiration of lymph nodes for pre-clinical studies of novel candidate AIDS vaccines".

Neutralizing antibodies correlated directly with the frequency and quality of B and T_{FH} cells but not with peripheral antibody titers, a standard tool to assess a vaccine’s effectiveness. “You definitely need those germinal centers and they have to work well to generate highly evolved, high affinity antibodies that can neutralize the virus,” says Havenar-Daughton.

Going forward, this work has demonstrated the value of an important new tool in vaccine trials for providing a window into what it will really take to make a successful HIV vaccine, and vaccines against other difficult infectious diseases.

About La Jolla Institute for Allergy and Immunology
La Jolla Institute for Allergy and Immunology is dedicated to understanding the intricacies and power of the immune system so that we may apply that knowledge to promote human health and prevent a wide range of diseases. Since its founding in 1988 as an independent, nonprofit research organization, the Institute has made numerous advances leading towards its goal: life without disease®.
